## S1 Formalization of Greenberg Correlation Universals

Here we describe how we selected the word order correlations in Table 1 of the main paper, and how we formalized these using syntactic relations defined by Universal Dependencies.

We base our formalization on the comprehensive study by Dryer [1].<sup>1</sup> Greenberg’s original study was based on 30 languages; more recently, Dryer [1] documented the word order correlations based on typological data from 625 languages. Dryer [1] formulated these universals as correlations between the order of objects and verbs and the orders of other syntactic relations. We test our ordering grammars for these correlations by testing whether the coefficients for these syntactic relations have the same sign as the coefficient of the verb-object relation. Testing correlations is therefore constrained by the degree to which these relations are annotated in UD. The verb-object relation corresponds to the *obj* relation defined by UD. While most of the other relations also correspond to UD relations, some are not annotated reliably. We were able to formalize eleven out of Dryer’s sixteen correlations in UD. Six of these could not be expressed individually in UD, and were collapsed into three coarse-grained correlations: First, tense/aspect and negative auxiliaries are together represented by the *aux* relation in UD. Second, the relation between complementizers and adverbial subordinators with their complement clauses is represented by the *mark* relation. Third, both the verb-PP relation and the relation between adjectives and their standard of comparison is captured by the *obl* relation.

The resulting operationalization is shown in Table S1. For each relation, we show the direction of the UD syntactic relation:  $\rightarrow$  indicates that the verb pattern is the head;  $\leftarrow$  indicates that the object pattern is the head.

As described in *Materials and Methods*, we follow Futrell et al. [5] in converting the Universal Dependencies format to a format closer to standard syntactic theory, promoting adpositions, copulas, and complementizers to heads. As a consequence, the direction of the relations *case*, *cop*, and *mark* is reversed compared to Universal Dependencies. For clarity, we refer to these reversed relations as *lifted\_case*, *lifted\_cop*, and *lifted\_mark*.

	Correlates with...		UD Relation	Greenberg [6]
	verb	object		
①	adposition	NP	$\xrightarrow{\text{lifted\_case}}$	3, 4
②	copula verb	predicate	$\xrightarrow{\text{lifted\_cop}}$	–
③	tense/aspect auxiliary	VP	$\xleftarrow{\text{aux}}$	16, 13
	negative auxiliary	VP		–
④	noun	genitive	$\xrightarrow{\text{nmod}}$	2, 23
⑤	noun	relative clause	$\xrightarrow{\text{acl}}$	24
⑥	complementizer	S	$\xrightarrow{\text{lifted\_mark}}$	–
	adverbial subordinator	S		–
⑦	adjective	std. of comp.	$\xrightarrow{\text{obl}}$	–
	verb	PP		22
⑧	‘want’	VP	$\xrightarrow{\text{xcomp}}$	15

Table S1: Greenbergian Correlations based on Dryer [1], with operationalizations with Universal Dependencies using the modified format of [5] (see text). For reference, we also provide the numbers of the closest corresponding universals stated in Greenberg’s original study, to the extent that this is possible.

**Excluded Correlations** Here, we discuss in more detail the five correlations from Dryer’s study that we had to exclude. First, we excluded three correlations that are not annotated reliably in UD, and are only relevant to some of the world’s languages: Question particles, plural words (i.e., independent plural markers), and articles. All three types of elements occur at most in parts of the 51 UD languages, and none of them is annotated reliably in those languages where they occur. Among these three types of elements, the one most prominent in our sample of 51 languages is articles, which occur in many European languages. However, UD subsumes them under the *det* relation, which is also used for other highly frequent elements, such as demonstratives and quantifiers. The other elements (question particles and plural words) are found at most in a handful of UD languages, and are not specifically annotated in these either.

We also excluded the verb-manner adverb correlation. UD does not distinguish manner adverbs from other elements labeled as adverbs, such as sentence-level adverbs and negation markers, whose ordering is very different from manner adverbs. All types of adverbs are unified under the *advmod* relation. In the real orderings in our sample of 51 UD languages, the dominant ordering of *advmod* almost always matches that of subjects – that is, *advmod* dependents are predominantly ordered after the verb only in VSO languages. This observed ordering behavior in the 51 languages is very different from that documented for manner adverbs by Dryer, showing that a large part of *advmod* dependencies as annotated in UD consists of elements that are not manner adverbs.

<sup>1</sup>Regarding the objections by Dunn et al. [2], we refer to the follow-ups by Levy and Daumé [3], and Croft et al. [4].

We further excluded the verb-subject correlation, which is not satisfied by much more than half of the world’s languages (51 % among those with annotation in the *World Atlas of Language Structures* [7], with clear violation in 35.4 %). It is satisfied only in 33% of our sample of 51 UD languages, as quantified using the grammars we extracted. Dryer [1] counts this as a correlation since he describes the distribution of subject order as an interaction between a weak correlation with object order, and a very strong dominance principle favoring SV orderings. We focus on the modeling of correlations, and leave dominance principles to future research. We therefore excluded this correlation here.

**Other Greenberg Universals** Greenberg [6] stated a total of 45 universals. Twenty of these concern the structure of individual words (as opposed to word order, which we focus on here), and many of those have been argued to be explained by the “dual pressures” idea [8]. The other 25 universals concern word order; Dryer [1] reformulated most of these as correlations with verb-object order; these form the basis of our formalization in Table S1. There are a few other well-supported word order universals that are not correlations with verb-object order. This includes dominance principles [9] such as the strong preference for subjects to precede objects. Furthermore, there has been interest in Greenberg’s universals 18 and 20, which describe correlations not with verb-object order, but of different elements of noun phrases [10, 11, 12]. Future work should examine whether these universals can also be linked to efficiency optimization.

## S2 Formalizing Communicative Efficiency

### S2.1 Derivation and Relation to Other Work

Here we discuss how our formalization of communicative efficiency relates to formalizations that have been proposed in the information-theoretic literature on language. Across the literature, the core idea is to maximize the **amount of information** that linguistic forms provide about meanings, while constraining **complexity and diversity** of forms:

$$\text{Informativity} - \lambda \cdot \text{Complexity} \quad (1)$$

with some differences in the precise formalization of these two quantities [13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28].

**Derivation of our Formalization** The basis for our precise formalization is the function proposed in [13, 14, 23, 27] as a general efficiency metric for communicative systems. If  $S$  denotes signals (e.g., words, sentences) and  $R$  denotes their referents (e.g., objects in a reference game), then this efficiency metric takes the form (notation slightly varies across these publications):

$$I[S, R] - \lambda \cdot H[S] \quad (2)$$

where  $I[S, R]$  describes the **informativity** of the signals  $S$  about their referents  $R$ , and  $H[S]$  describes the **complexity** of the communication system, and  $\lambda \geq 0$  trades off the two aspects of efficiency. While prior studies [13, 15, 21, 24] mostly considered settings where the signals  $S$  are individual words without further structure, the signals are entire sentences  $\mathcal{U}$  in our setting. The underlying messages  $R$  which the speaker aims to convey are the syntactic structures  $\mathcal{T}$ . By the principle of compositionality [29], the meaning of a sentence is a function of the meanings of the parts and how they are combined. The syntactic structure specifies how the meanings of words are combined; therefore, recovering the syntactic structure is a prerequisite to understanding a sentence correctly. Hence, substituting utterances  $\mathcal{U}$  for signals  $S$ , and syntactic structures  $\mathcal{T}$  for underlying messages  $R$ , into (2), we arrive at the following efficiency metric for word order:

$$R_{Eff} := R_{Pars} + \lambda \cdot R_{Pred} \quad (3)$$

where **parseability** is the amount of information that utterances provide about their underlying syntactic structures:

$$R_{Pars} := I[\mathcal{U}, \mathcal{T}] = \sum_{t,u} p(t, u) \log \frac{p(t|u)}{p(t)} \quad (4)$$

and **predictability** is the negative entropy or surprisal of the language:

$$R_{Pred} := -H[\mathcal{U}] = \sum_u p(u) \log p(u) \quad (5)$$

Parseability  $I[\mathcal{U}, \mathcal{T}]$  is higher if utterances provide more information about their underlying syntactic structure. Due to the identity  $I[\mathcal{U}, \mathcal{T}] = H[\mathcal{T}] - H[\mathcal{T}|\mathcal{U}]$ , parseability is maximized if every utterance can be parsed unambiguously – that is,

if the listener’s uncertainty about syntactic structures given received utterances,  $H[\mathcal{T}|\mathcal{U}]$ , is zero. Predictability  $-H[\mathcal{U}]$  is higher if the distribution over utterances is concentrated on a few utterances, and is maximized if there is just a single utterance. It is also equal to the negative average of surprisal, which is a strong and linear predictor of human language processing effort [30, 31, 32].

**Relation to Models of Semantic Typology** Our model of language efficiency is closely related to models of semantic typology that quantify the efficiency of mappings between concepts and individual words, applied with great success across different domains such color words, container names, and kinship terms [15, 19, 21, 22, 24, 28]. We discuss how our metric (2-3) relates to metrics assumed in this literature, and describe why (2-3) is most appropriate to our setting.

This efficiency metric (2-3) is equivalent to a deterministic version [33] of the Information Bottleneck approach, which has been applied to modeling word meaning across different domains by Zaslavsky et al. [24] and Zaslavsky et al. [28]. The Information Bottleneck models complexity using a mutual information term instead of the entropy appearing in (2). This mutual information formalization is appropriate to codes that are nondeterministic [24]. We assume deterministic grammars that transduce every underlying syntactic structure into one surface order; our model therefore corresponds to the deterministic version of the Information Bottleneck, which arises when the encoder is deterministic, and which uses the entropy as the complexity measure [33].

A few other approaches share the mutual information term for informativity in (2), while using complexity measures that are not explicitly information-theoretic. In studies of semantic typology by Regier et al. [34], Xu and Regier [19], Xu et al. [22], the complexity function is the number of different forms. As the entropy of a finite and uniform distribution is the logarithm of the number of objects, this complexity function arises from the entropy measure  $H[S]$  (2) in the special case where all forms are used at equal frequency. Notably, the models of Regier et al. [34] and Xu et al. [22] have since been reformulated successfully in the Information Bottleneck formalism [24, 28], bringing them even closer to our formalization of efficiency.

**Relation to Models of Language Evolution** Our model is also related to models of language evolution. Most closely related to our work, Kirby et al. [20] model language evolution as balancing the pressure towards simple languages with the pressure for languages to be informative about the intended meanings. Formally, their model studies a Bayesian language learner who infers a language  $h$  from data  $d$  according to  $P(h|d) \propto P(d|h)P(h)$ , where  $P(h)$  defines a prior distribution over languages, and  $P(d|h)$  is the likelihood of observed data  $d$  under the grammar  $h$ , assuming that speakers produce utterances pragmatically. The prior  $P(h)$  favors less complex languages; the likelihood  $P(d|h)$  favors languages that communicate meanings unambiguously. We now show that this model instantiates the basic objective (1). If the dataset  $d$  consists of observed pairs  $(t, f)$  of meanings  $t$  and forms  $f$ , and the language  $h$  defines a set of possible pairs  $(t, f)$ , then the log-likelihood as defined by their model can be written as follows (up to constants)<sup>2</sup>

$$\log P(d|h) = \sum_{(t,f) \in d} \log P(f|h,t) = \sum_{(t,f) \in d} \log P(f|h,t) \propto \sum_{(t,f) \in d} \log \frac{1}{|\{t' : (t', f) \in h\}|} = \sum_{(t,f) \in d} \log P(t|f) \quad (6)$$

where  $P(t|f)$  is the probability that the observed form  $f$  referred to meaning  $t$ , as the model assumes uniform meaning distributions and uniform choice of appropriate forms. Replacing the sum over the dataset  $d$  by the expectation over the idealized full distribution over meaning-form pairs, this can be rewritten as

$$-H[t|f] = I[t, f] - H[t] \quad (7)$$

where the first term is the mutual information between forms and meanings, as in our efficiency metric (2-3). The second term, the entropy of meanings, is a constant independent of the form-meaning mapping. The overall log probability assigned by the Bayesian learner thus comes out to (up to constants)

$$\log P(h|d) = I[t, f] + \lambda \log P(h) \quad (8)$$

where the prior  $P(h)$  favors simpler languages. This result shows that the model of Kirby et al. [20] predicts that language evolution favors languages optimizing a function of the form (1), with an informativity term identical to that of our model (2-3).

**Relation to Formalizations of Pragmatics** In addition to these models, which model the efficiency and evolution of communication systems, there is closely related work formalizing the optimal choice of specific utterances in context.

<sup>2</sup>We assume for simplicity that the error probability  $\epsilon$  in the model is equal to 0.

Our work is most closely related to the Rational Speech Acts model of pragmatic reasoning [16, 17, 18]. In line with the other models discussed here, it assumes that rational speakers choose utterances to optimize informativity about the referent object, and trade this off with the cost of the utterance, which is partly chosen to be the surprisal of the utterance [25, 26, 27]. Peloquin et al. [27] provide further discussion of the links between pragmatics and the efficiency metric (2-3).

**Relation to Models in Other Disciplines** Beyond the study of natural language, the efficiency metric (2) is also closely related to information-theoretic models in other disciplines. The tradeoff between informativity and complexity of communication systems is studied by Rate-distortion theory [35, 36]. The *Infomax Principle* derives parsimonious data representations by maximizing the mutual information between data and representations, subject to constraints on the representations [37]; a constraint on the representation entropy leads to a metric equivalent to (2) and to a version of the Free-Energy principle (see Section S3 in Friston [38]).

## S2.2 Choice of $\lambda$

In the efficiency objective (3)

$$R_{Eff} := R_{Pars} + \lambda R_{Pred} \quad (9)$$

the value of  $\lambda$  is constrained to be in  $[0, 1)$ . This means, surprisal must be weighted less strongly than parseability.

The reason is that greater values of  $\lambda$  can mathematically result in degenerate solutions. To show this, note that the following inequality always holds:

$$I[\mathcal{U}; \mathcal{T}] \leq H[\mathcal{U}]. \quad (10)$$

Therefore, if  $\lambda \geq 1$ , the efficiency objective satisfies  $R_{Eff} = I[\mathcal{U}; \mathcal{T}] - \lambda H[\mathcal{U}] \leq 0$ , and it takes the maximally possible value zero if there is only a single utterance  $\mathcal{U}$ , in which case both  $I[\mathcal{U}; \mathcal{T}]$  and  $H[\mathcal{U}]$  are zero. This is a degenerate language with only a single utterance, which is simultaneously used to convey all meanings. While the design of our word order grammars (see *Materials and Methods*) precludes a collapse of all syntactic structures to a single utterance, this shows that an objective with  $\lambda \geq 1$  cannot be a generally applicable description of the efficiency of communication systems. In conclusion,  $\lambda$  is constrained to be in  $[0, 1)$ , with values closer to 1 placing similar weights on both predictability and parseability, whereas values closer to 0 diminish the role of predictability.

In our experiments, we chose  $\lambda = 0.9$  as a mathematically valid value that puts similar weight on both predictability and parseability. While the computational cost of grammar optimization precluded repeating the experiment for many values of  $\lambda$ , we also examined word order predictions for grammars optimized for only parseability or only predictability, in order to tease apart predictions made by these two components. As shown in Table S4, each of the eight correlations is predicted by at least parseability or predictability, without any contradictory predictions. That is, at  $\lambda$  close to its maximal value, the predictions of optimizing the two scoring functions individually add up to the predictions of efficiency optimization.<sup>3</sup> Small values of  $\lambda$  correspond to the case where predictability plays no role, and only parseability is optimized (Table S4), in which case not all correlations are predicted (Figure S4). This is confirmed by converging evidence from our preregistered preliminary experiments in Figure S6.

## S3 Supplementary Analyses for Study 1

In Figure S1, we show the predictability-parseability planes for every one of the 51 languages, together with Pareto frontiers estimated from optimized grammars.

We z-transformed on the level of individual languages, normalizing the mean and SD parseability and predictability of the (1) real grammar, (2) the mean of predictability and parseability of all random grammars, (3) the grammar optimized for efficiency (at  $\lambda = 0.9$ , see Section S2.2), (4) grammar optimized for parseability only, and (5) grammar optimized for predictability only.

Within each language, we estimate the Pareto curve based on the points obtained by optimizing for (1) efficiency (at  $\lambda = 0.9$ , see Section S2.2), (2) parseability, and (3) predictability.

Figure 4 in the main paper shows the average of these per-language plots, with a kernel density estimate of the distribution of baseline grammars.

<sup>3</sup>Results from one of the preliminary experiments reported in Figure S6 show that results are stable to small variation of  $\lambda$ : Essentially equivalent predictions are obtained for  $\lambda = 1.0$ . While  $\lambda = 1.0$  is not a valid choice for communicative efficiency in general due to the possibility of collapse to a single utterance, our setting does not allow such a collapse, as the syntactic structure already determines which words are present in the sentence.

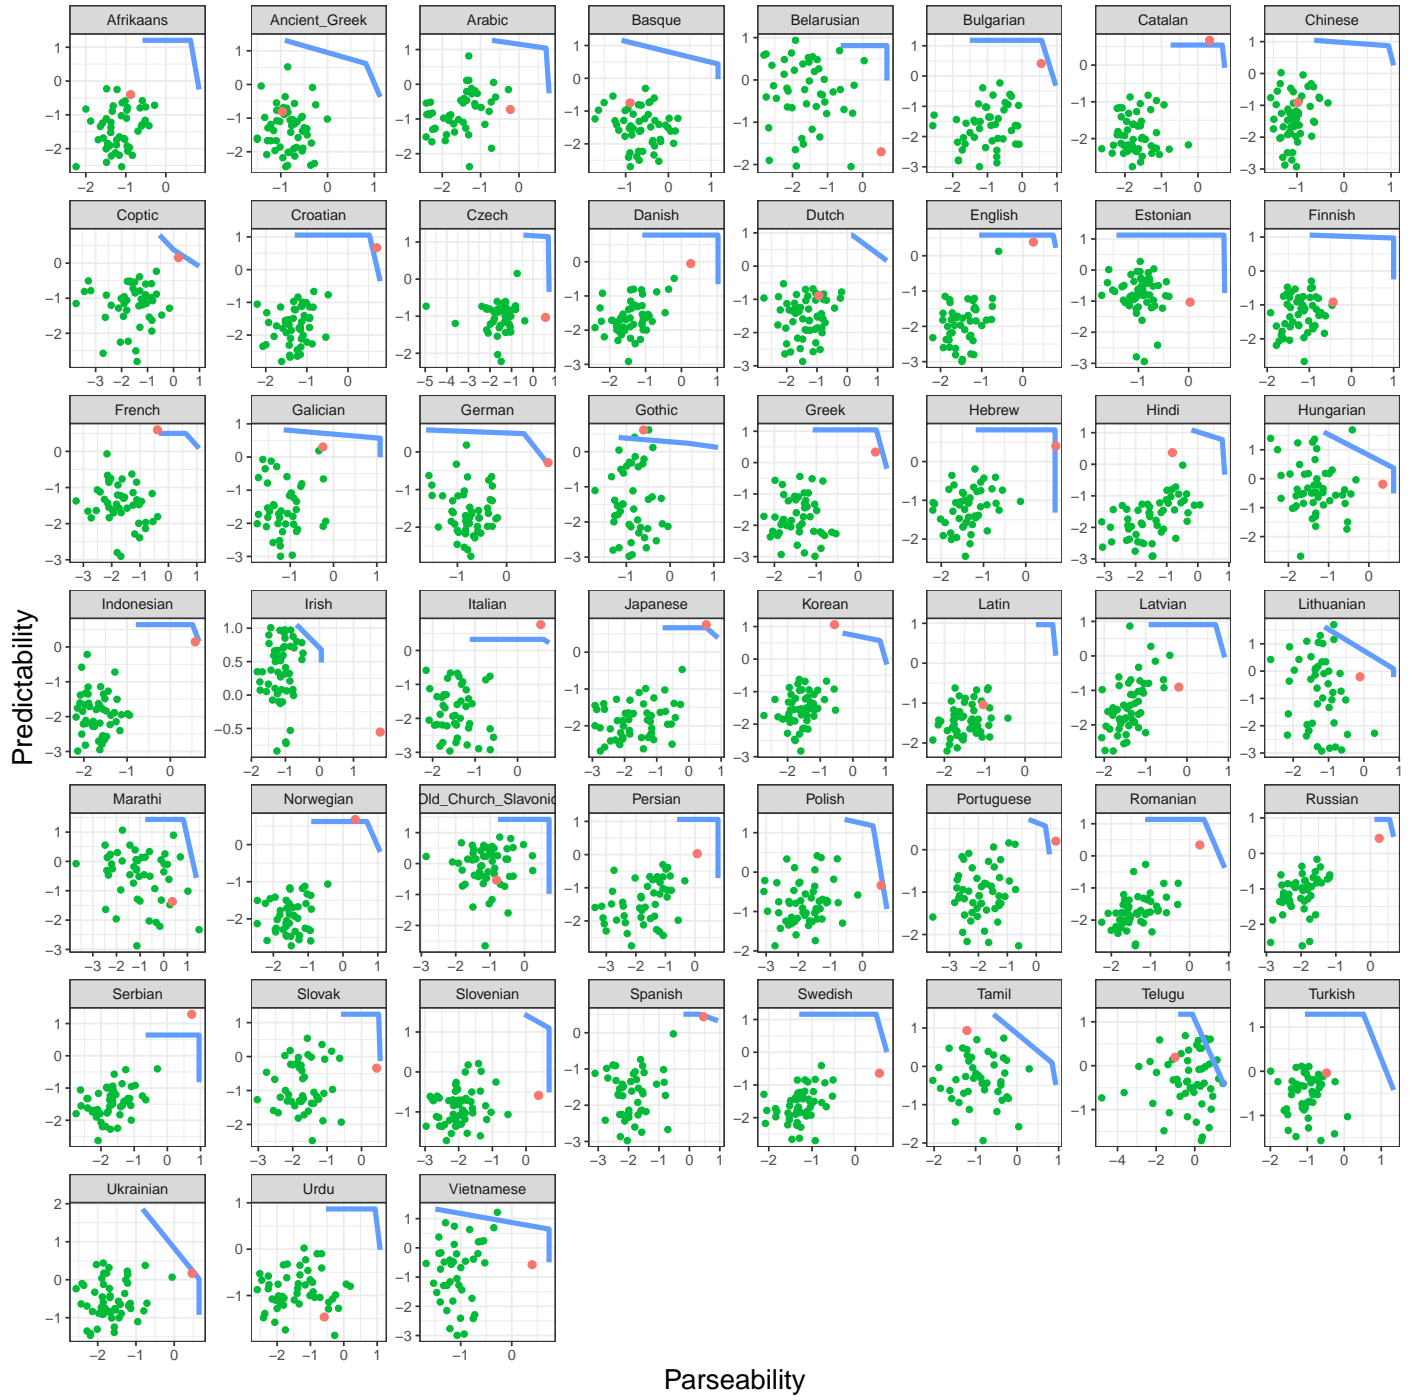

Figure S1: Predictability and parseability of 51 languages. Green: random baselines, Red: real grammar, blue: approximate Pareto frontier, computed from the optimized grammars.<sup>5</sup>All data are  $z$ -scored.

In the main paper, we tested whether real grammars are more efficient than the mean of random grammars, using a  $t$ -test. We also conducted the analysis using a Binomial test (one-sided), testing whether the real grammar is more efficient than the *median* of random grammars, avoiding any distributional assumption on the random grammars. As before, we used Hochberg’s step-up procedure (Note that the tests for different languages are independent, as different random grammars are evaluated for each language), with  $\alpha = 0.05$ . In this analysis, real grammars improved in parseability for 80% of languages, in predictability for 69% of languages, and in either of both in 92% of languages ( $p < 0.05$ , with Bonferroni correction). In Table S2, we provide per-language results for the  $t$ -tests and binomial tests.

## S4 Supplementary Analyses for Study 2

### S4.1 Correlation between Universals and Efficiency

In Figure S2, we plot efficiency, parseability, and predictability (all are  $z$ -scored within language, as in Study 1) as a function of the number of satisfied correlations, for the real grammars of the 51 languages.

We found very similar results using Spearman’s rank correlation (Efficiency:  $\rho = 0.59$ ,  $p = 9.8 \cdot 10^{-6}$ ; Parseability:  $\rho = 0.55$ ,  $p = 4.7 \cdot 10^{-5}$ ; Predictability:  $\rho = 0.36$ ,  $p = 0.012$ ).

Figure S2: Correlation between the number of satisfied correlations ( $x$ -axis) and efficiency, parseability, and predictability ( $y$ -axis), for the 51 real languages.

### S4.2 Predictions for Individual Languages

We show predictions for the eight correlations on the level of individual languages in Figure S3. We obtained these predictions for individual languages and each of the eight relations as follows. For each language and each of the objective functions (efficiency, predictability, parseability), we considered the optimized grammar that yielded the best value of this objective function among the eight optimized grammars (i.e., the grammar where the optimization procedure had been most successful). We interpreted this grammar as verb-object or object-verb depending on the order in the real grammar of the language.

### S4.3 Regression for Predicted Correlations

**Bayesian Mixed-Effects Regression** We modeled the probabilities  $p_{L,j}$  that a grammar optimized for data from language  $L$  satisfies the  $j$ -th correlation ( $j = 1, \dots, 8$ ) using a multilevel logistic model [39], with random intercepts for the language for whose data the grammar had been optimized, and for its language family, annotated according to <http://universaldependencies.org/>. Formally,

$$\text{logit}(p_{L,j}) = \alpha_j + u_{L,j} + v_{fL,j} \quad (11)$$

<sup>5</sup>Note that, in a few languages, the real grammar is at a position slightly *beyond* the estimated Pareto frontier. This can be attributed to two reasons: First, stochastic gradient descent introduces noise due to its stochasticity and will only approximately find an optimal solution; second, for some corpora, there may be some degree of distributional mismatch between the training partitions (on which grammars are optimized) and held-out partitions (on which efficiency is estimated). This in particular applies to very small corpora such as Irish (121 training sentences).

Language	Pred. (t)	Parse. (t)	Pred. (Binomial)			Parseab. (Binomial)

Table S2: Per-language results in Study 1. For each language, we show the following: (1)  $p$ -values obtained from a one-sided  $t$ -test, for the null that the mean predictability/parseability of random grammars is at least as high as that of the real grammar. (2) Results from one-sided binomial tests, for the null that the the real grammar is better than at most 50% of random grammars. In addition to the  $p$ -value, we report point estimate and 95% confidence interval for the fraction of random grammars that have values below real grammars.

Figure S3: Order of the eight correlates across 51 languages, in the real grammars (left) and predicted by optimizing for efficiency, predictability, parseability (right). Dark blue: Verb patterner *precedes* object patterner (English, Arabic, ...). Light blue: Verb patterner *follows* object patterner (Japanese, Hindi , ...). White cells indicate that the relation is not annotated in the dataset for the given language.

	Prevalence	Bayesian			Frequentist			
		Mean	SD	$p(\beta \leq 0)$	$\beta$	SE	$z$	p
①	0.779	1.449	0.273	$< 1 \times 10^{-4}$	1.395	0.222	6.277	$3.5 \times 10^{-10}$

Table S3: Detailed results for Bayesian and Frequentist mixed-effects analyses for the eight correlations. We show (1) the raw prevalence of each correlation in the optimized grammars (8 grammars for each of the 51 languages), (2) for the Bayesian analysis, we provide posterior mean and SD of  $\beta$ , and the posterior probability that  $\beta$  has the opposite sign, (3) for the Frequentist analysis, we provide the point estimate, SE,  $z$ , and  $p$ -values (2-sided). The frequentist analysis confirms the results of the Bayesian analysis.

where  $f_L$  is the language family of  $L$ . The intercepts  $\alpha_j$  ( $j = 1, \dots, 8$ ) encode the population-level prevalence of the correlations when controlling for differences between datasets from different languages and language families;  $u_{L,j}$ ,  $v_{f_L,j}$  encode per-language and per-family deviations from the population-level intercept  $\alpha_j$ .

Following the recommendations of [40, 41], we used as a very weakly informative prior a Student’s  $t$  prior with  $\nu = 3$  degrees of freedom, mean 0, and scale  $\sigma = 10$  (i.e., the PDF  $p$  is  $\frac{1}{\sigma} p_3(x/\sigma)$ , where  $p_3$  is the PDF of the  $t$ -distribution with  $\nu = 3$ ). We used this prior for  $\alpha_j, \sigma_{L,j}, \tau_{L,j}$ . A correlation that holds in 90% of cases would correspond to an intercept  $\alpha \approx 2.19$  in the logistic model, well within the main probability mass of the prior.

We modeled full covariance matrices of per-language and per-family random intercepts over all eight correlations. We placed an LKJ prior ( $\eta = 1$ ) on these matrices, as described in [41]. We used MCMC sampling implemented in Stan [42, 43] using the R package `brms` [44]. We ran four chains, with 5000 samples each, of which the first 2500 were discarded as warmup samples. We confirmed convergence using  $\hat{R}$  and visual inspection of chains [39].

We obtained the posterior density plots in Table 2 (Main Paper) and in Figure (S4) by applying the logistic transformation ( $x \mapsto \frac{1}{1+\exp(-x)}$ ) to the posterior samples of  $\alpha_j$  (11). As the logistic transformation is inverse to the logit transform (11), this corresponds to the posterior distribution of the prevalence (between 0.0 and 1.0) of each correlation, controlling for languages and language families.

**Robustness** To ascertain the robustness of our results, we also conducted a frequentist analysis using `lme4` [45]. For each of the correlations, we conducted a logistic mixed-effects analysis predicting whether a grammar satisfies the correlation, with random effects of language and language family. The results are shown in Table S3 together with those of the Bayesian analysis. The frequentist analysis agrees with the Bayesian model; all eight correlations are predicted to hold in more than half of the optimized grammars ( $p < 0.01$  each).

Note that the Bayesian analysis also estimates a posterior distribution of the number of satisfied correlations (see Figure S4), providing an elegant solution to the multiple-comparisons problem arising from analysing the eight correlation.

#### S4.4 Comparing Efficiency to its Components

In Figure S4, we plot the posterior distribution of the number of correlations predicted to hold in most optimized grammars, as obtained from the Bayesian regression. For each posterior sample, we say that the  $j$ -th correlation holds if the value of  $\alpha_j$  in that posterior sample is positive. In the figure, we plot the fraction of posterior samples in which a given number of correlations is satisfied. In addition to grammars optimized for efficiency, we also report the result for grammars optimized for predictability and for parseability alone. Efficiency predicts all eight correlations with high posterior probability; predictability and parseability alone do not.

#### S4.5 Results on all UD Relations

In this section, we provide the predicted prevalence of correlations between the *obj* dependency and all UD dependency types, along with the expected prevalence according to typological studies. We also report results for grammars optimized for predictability and parseability individually.

Figure S4: Posterior of the number of correlations correctly predicted by efficiency and its components, in the Bayesian multivariate mixed-effects logistic regression with random effects for languages and language families. We show results for grammars optimized for only Predictability (left), only Parseability (center), and full Efficiency (right).

We considered all UD syntactic relations occurring in at least two of the 51 languages. In Table S4, we present the data for the eight correlations discussed in the main paper, and for those other relations for which the typological literature provides data.<sup>6</sup> Additionally, in Table S5 we present data for the other UD relations, for which either no typological data is available, or which are not linguistically meaningful.

## S4.6 Previous Experiments

In Table S6 we report the results of our two previous, preregistered, simulations<sup>7</sup> together with results from the main experiment. These experiments all had the same setup described in Section S6, which was fixed before starting simulations; differences are that (1) one simulation places fully equal weight on parseability and predictability ( $\lambda = 1.0$ ), and (2) the final experiment uses three random seeds per grammar. Results across all three experiments agree; jointly optimizing grammars for parseability and predictability produces all eight correlations.

## S5 Creating Optimized Grammars

In this section, we describe the method we employ for creating grammars that are optimized for efficiency, and how we extract grammars describing the actual ordering rules of languages. We carry out grammar optimization in an extended space of grammars that interpolates continuously between different grammars (Section S5.1). More specifically, we include probabilistic relaxations of grammars, which describe probability distributions over different ways of ordering a syntactic structure into a sentence. This makes efficiency a *differentiable* function of the grammar parameters, and enables efficient optimization with stochastic gradient descent, as we describe in Section S5.3.

This method addresses a major challenge noted in previous work optimizing grammars, namely that the predictability (and parseability) of an individual sentence depends on the entire distribution of the language. Previously, Gildea and Jaeger [46] optimized grammars for dependency length and trigram surprisal using a simple hill-climbing method on the grammar parameters, which required reestimating the trigram surprisal model in every iteration. Such a method would be computationally prohibitive for efficiency optimization, as it would require reestimating the neural network models after every change to the grammar, which would amount to reestimating them hundreds or thousands of times per grammar. Our method, by allowing for the use of stochastic gradient descent, addresses this challenge, as we describe in Section S5.3.

<sup>6</sup>The *aux* syntactic relation in UD has the auxiliary (verb-patterner) as its dependent, and has direction *opposite* to the auxiliary-verb relation ③. Therefore, this relation is *anti-correlated* with the verb-object relation, while ③ is *correlated*. For simplicity, we display this as a correlation in this table.

<sup>7</sup><http://aspredicted.org/blind.php?x=8gp2bt>, <https://aspredicted.org/blind.php?x=bg35x7>. For the results of the Locality simulations described in the first preregistration, see the Dependency Length Minimization results in Table S10, with discussion in Section S10.

	Relation	Real	Pred	Pars	Efficiency	Expected Prevalence
①	lifted_case					> 50% [1]
②	lifted_cop					> 50% [1]
③	aux					> 50% [1]
④	nmod					> 50% [1]
⑤	acl					> 50% [1]
⑥	lifted_mark					> 50% [1]
⑦	obl					> 50% [1]
⑧	xcomp					> 50% [1]
	advcl					> 50% [6, 83]
	ccomp					> 50% (cf. [84])
	csubj					> 50% (cf. [84])
	nsubj					See Section S1
	amod					≈ 50% [1]
	nummod					≈ 50% [85, 89A, 83A]

Table S4: Predictions on UD relations with predictions from the typological literature. The first section contains the eight correlations discussed in the main paper (See Section S1); the second section provides other relations for which predictions are available. The ‘Real’ column provides the prevalence among the 51 languages in the Universal Dependencies data. We provide posterior prevalences for grammars optimized for Efficiency, and for grammars optimized for Pars(eability) and Pred(ictability) alone, obtained from the Bayesian mixed-effects analysis controlling for languages and language families (as in Table 2 of the main paper). In the last column, we indicate what prevalence is expected according to the typological literature.

Relation	Real	Pred	Pars	Efficiency	Expected Prevalence
appos					Unknown
lifted_cc					Unknown
expl					Unknown
iobj					Unknown
vocative					Unknown
compound					Uninterpretable
det					Uninterpretable
dislocated					Uninterpretable
dep					Uninterpretable
advmod					Uninterpretable
conj					UD Artifact
discourse					UD Artifact
fixed					UD Artifact
flat					UD Artifact
goeswith					UD Artifact
list					UD Artifact
orphan					UD Artifact
parataxis					UD Artifact
reparandum					UD Artifact

Table S5: Predictions on UD relations for which no predictions are available in the typological literature. “Uninterpretable” UD relations are those which collapse so many different linguistic relationships that they are not linguistically meaningful. “UD artifact” relations are those whose order is determined strictly by UD parsing standards, such that their order is not linguistically meaningful: these include dependencies such as the connection between two parts of a word that have been separated by whitespace inserted as a typo (*goeswith*). We provide results for grammars optimized for Efficiency, and for grammars optimized for Pars(eability) and Pred(ictability) alone.

	$\lambda = 0.0$	$\lambda = 0.9^1$	$\lambda = 0.9^2$	$\lambda = 1.0^3$
①				
②				
③				
④				
⑤				
⑥				
⑦				
⑧				

Table S6: Results from optimization experiments for different values of  $\lambda$ , including our two previous preregistered experiments (Section S4.6). For comparison, we also show results for  $\lambda = 0$ , corresponding to optimizing for parseability only (same results as reported in Tables (S4-S5)). For  $\lambda = 0.9$ , we report results from one preliminary preregistered experiment (left) and the final experiment (right). For  $\lambda = 1.0$ , we report the other preliminary preregistered experiment. Giving similar weight to parseability and predictability – that is,  $\lambda$  close to 1 – results in more accurate word order predictions than choosing a small value of  $\lambda$  such as  $\lambda = 0.0$ . Note that  $\lambda$  cannot take values smaller than zero, or greater than one, see Section S2.2.

## S5.1 Differentiable Ordering Grammars

We extended the parameter space of grammars by continuously interpolating between grammars, making efficiency a *differentiable* function of grammar parameters. The parameters of such a **differentiable word order grammar** are as follows. For each dependency label type  $\tau$ , we have (1) a **Direction Parameter**  $a_\tau \in [0, 1]$ , and (2) a **Distance Parameter**  $b_\tau \in \mathbb{R}$ . Each dependent is ordered on the left of its head with probability  $a_\tau$  and to the right with probability  $1 - a_\tau$ . Then for each set of co-dependents  $\{s_1, \dots, s_n\}$  placed on one side of a head, their order outward from the head is determined by iteratively sampling from the distribution  $\text{softmax}(b_{\tau_1}, \dots, b_{\tau_n})$  ([47], p. 184) without replacement.

If  $a_\tau \in \{0, 1\}$ , and the distances between values of  $b_\tau$  (for different  $\tau$ ) become very large, such a differentiable grammar becomes deterministic, assigning almost full probability to exactly one ordering for each syntactic structure. In this case, the grammar can be converted into an equivalent grammar of the form described in Materials and Methods, by extracting a single parameter in  $[-1, 1]$  for each relation  $\tau$ .

We provide an example in Figure S5, illustrating grammar parameters for the relations in Figure 3 of the main paper. Note that the grammatical formalism simplifies some aspects of the word order regularities of natural languages. For instance, it does not represent cases where ordering varies between main and embedded clauses, as it does not condition ordering decisions on the larger context. More complex and powerful ordering grammar models have been proposed [48, 49]; however, they have similar limitations, and for our purposes, the model adopted here has the advantage of being simple and interpretable.

Relation	English			Japanese		
	Par.	$a_\tau$	$b_\tau$	Par.	$a_\tau$	$b_\tau$
object ( <i>obj</i> )	0.1	0.04	-1.46	-0.1	0.99	-0.72
oblique ( <i>obl</i> )	0.3	0.13	1.25	-0.3	0.99	0.73
case ( <i>lifted.case</i> )	0.2	0.07	-0.89	-0.2	0.92	0.02

Figure S5: Sample Coefficients from grammars extracted from the real English and Japanese orderings (Section S5.2), for the relations occurring in Figure 3 (Main Paper). We show parameters in  $[-1, 1]$  for deterministic word order grammars as described in *Materials and Methods*, and the coefficients  $(a_\tau, b_\tau)$  for corresponding differentiable ordering grammars. For the deterministic grammars (‘Par.’), positive coefficients indicate that the dependent will be placed after the head. For the differentiable grammars,  $a_\tau > 0.5$  indicates predominance of ordering of dependents before heads, and larger  $b_\tau$  indicates greater distance between head and dependent.

## S5.2 Extracting Grammars from Datasets

We extract grammars for each actual language by fitting a differentiable ordering grammar maximizing the likelihood of the observed orderings. To prevent overfitting, we regularize each  $a_\tau, b_\tau$  with a simple Bayesian prior  $\text{logit}(a_\tau) \sim \mathcal{N}(0, 1)$ ,  $b_\tau \sim \mathcal{N}(0, 1)$ . We implemented this regularized optimization as mean-field ELBO variational inference in Pyro [50]. We then extract the posterior means for each parameter  $a_\tau, b_\tau$ , and convert the resulting differentiable grammar into an ordinary ordering grammar.

We validated the extracted grammars by comparing the dominant orders of six syntactic relations that are also annotated in the World Atlas of Linguistic Structures (WALS, [51]). Among the eight Greenbergian correlations that we were able to test, five are annotated in WALS: adpositions, complementizers, relative clauses, genitives, and oblique PPs. In Table S7, we compare our grammars with WALS on these five relations, and the verb-object relation. WALS has data for 74% of the entries<sup>8</sup>, and lists a dominant order for 91% of these. The grammars we extracted from the corpora agree with WALS in 96 % of these cases.

## S5.3 Optimizing Grammars for Efficiency

In this section, we describe how we optimized grammar parameters for efficiency. A word order grammar can be viewed as a function  $\mathcal{L}_\theta$ , whose behavior is specified by parameters  $\theta$ , which takes an unordered dependency tree  $t$  as input and produces as output an ordered sequence of words  $u = \mathcal{L}_\theta(t)$  linearizing the tree. More generally, if  $\mathcal{L}_\theta$  is a differentiable ordering grammar (Section S5.1), then  $\mathcal{L}_\theta(t)$  defines a *probability distribution*  $p_{\mathcal{L}_\theta}(u|t)$  over ordered sequences of words  $u$ . In the limit where  $\mathcal{L}_\theta$  becomes deterministic, the distribution  $p_{\mathcal{L}_\theta}(u|t)$  concentrates on a single ordering  $u$ .

Recall the definition of efficiency

$$R_{\text{Eff}} := R_{\text{Pars}} + \lambda R_{\text{Pred}} \quad (12)$$

where

$$R_{\text{Pars}} := \mathbb{I}[\mathcal{U}, \mathcal{T}] = \sum_{t, u} p(t, u) \log \frac{p(t|u)}{p(t)} \quad (13)$$

$$R_{\text{Pred}} := -\mathbb{H}[\mathcal{U}] = \sum_u p(u) \log p(u) \quad (14)$$

where  $t \sim \mathcal{T}$  is the distribution over syntactic structures as found in databases of the language, and  $u \sim p_{\mathcal{L}_\theta}(u|t)$  denotes the corresponding linearized sentences.

These quantities are estimated using two neural models, as described in Section S6: A **parser** recovers syntactic structures from utterances by computing a distribution  $p_\phi(t|u)$ , parameterized via parser parameters  $\phi$ . The degree to which a parser with parameters  $\phi$  succeeds in parsing a sentence  $u$  with structure  $t$  is<sup>9</sup>

$$R_{\text{Pars}}^\phi(u, t) = \log p_\phi(t|u) \quad (15)$$

<sup>8</sup>Serbian and Croatian are listed as a single language Serbian-Croatian in WALS. In the table, we compare those with the grammar we extracted for Croatian, noting that it fully agrees with the Serbian grammar.

<sup>9</sup>Note that, in the definition of  $R_{\text{Pars}}$  (26), the term  $p(t)$  is a constant independent of  $\phi$  and the word order grammar  $\mathcal{L}_\theta$ ; it can therefore be ignored in the optimization process.

Table S7: Comparing grammars extracted from databases to linguistic judgments in the World Atlas of Linguistic Structures. For each of the six syntactic relation, the first column provides the ordered coded in the extracted grammar; the second column provides the order coded in WALS (DH for dependent-head, HD for head-dependent order). ‘?’ indicates that WALS has no data. \* indicates that WALS does not list a dominant order; as Dryer [52] describes, this can mean that neither order is dominant in the language, or that insufficient data was available when compiling WALS. Finally, ‘–’ indicates that the relation does not occur in the Universal Dependencies corpus.

A **language model**, with some parameters  $\psi$ , calculates the word-by-word surprisal of an utterance:

$$R_{Pred}^\psi(u) = \sum_{i=1}^{|u|} \log p_\psi(u_i | u_{1...i-1}) \quad (16)$$

Using this and Gibbs’ inequality [53], we can rewrite Efficiency (12), for a given grammar  $\theta$ , equivalently into the parseability and predictability achieved with the best parser and language models:

$$R_{Eff}^\theta := \max_{\phi, \psi} R_{Eff}^{\theta, \phi, \psi} \quad (17)$$

where we have written

$$R_{Eff}^{\theta, \phi, \psi} := \mathbb{E}_{t \sim \mathcal{T}} \mathbb{E}_{u \sim p_{\mathcal{L}_\theta}(u|t)} \left[ R_{Pars}^\phi(u, t) + \lambda R_{Pred}^\psi(u) \right] \quad (18)$$

In order to find an optimal grammar  $\theta$ , we thus need to compute

$$\arg \max_{\theta} R_{Eff}^\theta = \arg \max_{\theta} \max_{\phi, \psi} R_{Eff}^{\theta, \phi, \psi} \quad (19)$$

Importantly,  $R_{Eff}^{\theta, \phi, \psi}$  is differentiable in  $\theta, \phi, \psi$ :

$$\partial_\theta R_{Eff}^{\theta, \phi, \psi} = \mathbb{E}_t \mathbb{E}_{u \sim p_{\mathcal{L}_\theta}(u|t)} \left[ [\partial_\theta \log p_{\mathcal{L}_\theta}(u|t)] \cdot \left( R_{Pars}^\phi(u, t) + \lambda R_{Pred}^\psi(u) \right) \right] \quad (20)$$

$$\partial_\phi R_{Eff}^{\theta, \phi, \psi} = \mathbb{E}_t \mathbb{E}_{u \sim p_{\mathcal{L}_\theta}(u|t)} \left[ \partial_\phi R_{Pars}^\phi(u, t) \right] \quad (21)$$

$$\partial_\psi R_{Eff}^{\theta, \phi, \psi} = \mathbb{E}_t \mathbb{E}_{u \sim p_{\mathcal{L}_\theta}(u|t)} \left[ \lambda \cdot \partial_\psi R_{Pred}^\psi(u) \right] \quad (22)$$

where (20) is derived using the *score-function* or *REINFORCE* theorem [54]. Note that the derivatives inside the expectations on the right hand sides can all be computed using backpropagation for our neural network architectures.

We can therefore apply stochastic gradient descent to jointly optimize  $\theta, \phi, \psi$ : In each optimization step, we sample a dependency tree  $t$  from the database, then sample an ordering from the current setting of  $\theta$  to obtain a linearized sentence  $\mathbf{w} \sim p_\theta(\cdot|t)$ . Then we do a gradient descent step using the estimator given by the expressions in the square brackets in (20-22).

Optimizing for only parseability (or predictability) is very similar – in this case, the terms involving  $R_{Pred}^\phi$  (or  $R_{Pars}^\psi$ ) are removed.

At the beginning of the optimization procedure, we initialize all values  $a_\tau := 0.5$ ,  $b_\tau := 0$  (except for the *obj* dependency, for which we fix  $a_\tau$  to 0 or 1, see Section S6). The neural parser and language model are also randomly initialized at the beginning of optimization. Empirically, we observe that optimizing differentiable ordering grammars for efficiency leads to convergence towards deterministic behavior, allowing us to extract equivalent deterministic grammars as described in Section S5.1.

See Section S6, paragraph ‘Optimization Details’ for the stopping criterion and learning rates used in this optimization scheme.

## S6 Neural Network Architectures

In this section, we describe the details of the neural network architectures. Choices follow standard practice in machine learning. All choices, except where explicitly noted otherwise, were made before evaluating word order properties, and the efficiency of real grammars.

**Estimating Predictability** We choose a standard LSTM language model [55, 56], as such recurrent neural models are the strongest known predictors of the surprisal effect on human processing effort [71, 72]. This model uses a recurrent neural network to compute the predictability of a sentence  $u = u_1...u_n$ <sup>10</sup>:

$$\log p_\psi(u) = \sum_{i=1}^n \log p_\psi(u_i | u_{1...i-1}) \quad (23)$$

<sup>10</sup>Technically,  $u_1...u_{n-1}$  are words, and  $u_n$  is an end-of-sentence token, to ensure the probability distribution over all sentences is normalized.

where  $\psi$  are the parameters of the recurrent LSTM network, optimized on training data (see paragraph ‘Optimization Details’).

We estimate the average predictability of a language as a Monte Carlo estimate on held-out data:

$$R_{Pred} := -H[\mathcal{U}] = \sum_u p(u) \log p_\psi(u) \approx \frac{1}{|\text{Heldout Data}|} \sum_{u \in \text{Heldout Data}} \log p_\psi(u) \quad (24)$$

by averaging over all sentences  $u$  occurring in the corpus.

For computational reasons, we restrict the vocabulary to the most frequent 50,000 words in the treebanks for a given language. Given the moderate size of the corpora, this limit is only attained only for few languages. In each time step, the input is a concatenation of embeddings for the word, for language-specific POS tags, and for universal POS tags. The model predicts both the next word and its POS tags in each step. Using POS tags is intended to prevent overfitting on small corpora.

**Estimating Parseability** We use a biaffine attention parser architecture [57, 58, 59]. This architecture is remarkably simple: the words of a sentence are encoded into context-sensitive embeddings using bidirectional LSTMs, then a classifier is trained to predict the head for each word. The classifier works by calculating a score for every pair of word embeddings  $(w_i, w_j)$ , indicating the likelihood that the  $j$ th word is the head of the  $i$ th word. This is a highly generic architecture for recovering graph structures from strings, and is a simplification of graph-based parsers which reduce the parsing problem to a minimal spanning tree problem [60]. The parseability of a sentence  $u = u_1 \dots u_n$  with syntactic structure  $t$  is computed as

$$\log p_\phi(t|u) = \sum_{i=1}^n \log p_\phi(\text{head}_i, \text{label}_i|u, i) \quad (25)$$

where  $\text{head}_i \in \{\text{ROOT}, 1, \dots, n\}$  is the index of the head of  $u_i$  in the syntactic structure, and  $\text{label}_i$  is its syntactic relation as formalized in UD;  $\phi$  denotes the parameters estimated on the training data (see paragraph ‘Optimization Details’). The overall parseability is estimated as a Monte Carlo estimate on held-out data:

$$R_{Pars} := I[\mathcal{U}, \mathcal{T}] = \sum_{t,u} p(t, u) \log \frac{p_\phi(t|u)}{p(t)} = \frac{1}{|\text{Heldout Data}|} \sum_{t,u \in \text{Heldout Data}} \log \frac{p_\phi(t|u)}{p(t)} \quad (26)$$

The constant  $p(t)$  only depends on the language (but not on the word order rules), and can thus be ignored when comparing different grammars applied to the same language, and when optimizing grammars for a given language; we therefore do not attempt to explicitly estimate it.

To reduce overfitting on small corpora, we choose a delexicalized setup, parsing only from POS tags. Preliminary experiments showed that a parser incorporating word forms overfitted long before the ordering grammar had converged; parsing from POS tags prevents early overfitting. This decision was made before evaluating word order properties.

**Hyperparameters** Neural network models have hyperparameters such as the number of hidden units, and the learning rate. For predictability and parseability optimization, we first selected hyperparameters on the respective objectives for selected languages on the provided development partitions. These parameters are shown in Table S8. Then, for each language and each objective function, we created eight random combinations of these selected hyperparameter values, and selected the setting that yielded the best value of the respective objective function (efficiency, predictability, parseability) on the language. We then used this setting for creating optimized word order grammars.

All word and POS embeddings are randomly initialized with uniform values from  $[-0.01, 0.01]$ . We do not use pretrained embeddings [61]: While these could improve performance of language models and parsers, they would introduce confounds from the languages’ actual word orders as found in the unlabeled data.

**Improved Unbiased Gradient Estimator** We employ two common variance reduction methods to improve the estimator (20), while keeping it unbiased. For predictability, note that the surprisal of a specific word only depends on the preceding words (not on the following words), and thus only depends on ordering decisions made up to that word. We represent the process of linearizing a tree as a dynamic stochastic computation graph, and use these independence properties to apply the method described in Schulman et al. [62] to obtain a version of (20) with lower variance. Second, we use a word-dependent moving average of recent per-word losses (the word’s surprisal in the case of predictability, and the negative log-probability of the correct head and relation label in the case of parseability) as control variate [54]. These two methods reduce the variance of the estimator and thereby increase the speed of optimization and reduce training time, without biasing the results. For numerical stability, we represent  $a_\tau \in [0, 1]$  via its logit  $\in \mathbb{R}$ . Furthermore, to

Optimization	Learning Rate Momentum	5e-6, 1e-5, 2e-5, 5e-5 0.8, 0.9

Table S8: Hyperparameters

encourage exploration of the parameter space, we add an entropy regularization term [63] for each Direction Parameter  $a_\tau$ , which penalizes  $a_\tau$  values near 0 or 1. The weight of the entropy regularization was chosen together with the other hyperparameters.<sup>11</sup>

These techniques for improving (20) are well-known in the machine learning literature, and we fixed these before evaluating optimized grammars for word order properties.

**Optimization Details** We update word order grammar parameters  $\theta$  using Stochastic Gradient Descent with momentum. For the language model parameters  $\phi$ , we use plain Stochastic Gradient Descent without momentum, as recommended by Merity et al. [64]. For the parser parameters  $\psi$ , we use Adam [65], following Dozat et al. [59]. The learning rates and other optimization hyperparameters were determined together with the other hyperparameters.

All corpora have a predefined split in training and held-out (development) sets. We use the training set for optimizing parameters, and apply Early Stopping [66] using the held-out set.

For **estimating the parseability or predictability** of a given grammar, we optimize the neural model on data ordered according to this grammar, and report the parseability/predictability on the held-out set to avoid overfitting to the training set. For Early Stopping, we evaluate on the held-out set at the end of every epoch.

For **optimizing grammars**, we jointly apply gradient descent to the grammar parameters and the neural models, using the gradient estimator (20-22). For Early Stopping, we evaluate on the held-out set in intervals of 50,000 sentences, using a Monte-Carlo estimate of  $R_{Eff}^{\theta, \phi, \psi}$  (S5.3), sampling a single linearized sentence for each syntactic structure in the held-out set. When reporting the parseability/predictability of an optimized grammar, we evaluate these values for its fully deterministic version (Section S5.1) to allow fair comparison with baseline grammars.

The choice of optimization methods and the stopping criterion were fixed before we investigated language efficiency or word order correlations.

**Optimized Grammars** As described in the main paper, for each language, we created 8 optimized languages for each optimization criterion. We enforced balanced distribution of object-verb and verb-object ordering among optimized languages by fixing  $a_\tau$  for the *obj* dependency to be 0.0 in four of these languages, and 1.0 in the other four. This maximizes statistical precision in detecting and quantifying correlations between the verb-object relation and other relations.

For efficiency optimization, for each grammar, we ran efficiency optimization with three different random seeds, selecting among these the seed that yielded the best overall efficiency value. We did this in order to control for possible variation across random seeds for the stochastic gradient descent optimization method. As described in our preregistration <http://aspredicted.org/blind.php?x=ya4qf8>, this choice was made after conducting a preliminary version of Study 2 reported in Section S4.6; results reported there show qualitatively identical results regarding the prediction of the eight word order correlations by efficiency optimization.

## S7 Robustness to different language models and parsers

Here we take up the question of the extent to which our results are dependent on the particular parser and language model used in the optimization process. We want to know: when we optimize a word order grammar for efficiency, have

<sup>11</sup>Explored values: 0.0001, 0.001.

we produced a language which is highly efficient *in general*, or one which is highly efficient *for a specific parser*? We wish to argue that natural language syntax is optimized for efficiency in general, meaning that syntactic trees are highly recoverable from word orders in principle. If it turns out that our optimized languages are only optimal for a certain parser from the NLP literature, then we run the risk of circularity: it may be that the reason this parser was successful in the NLP literature was because it implicitly encoded word order universals in its inductive biases, and thus it would be no surprise that languages which are optimized for parseability also show those universals.

In this connection, we note that the parser and language model architectures we use are highly generic, and do not encode any obvious bias toward natural-language-like word orders. The LSTM language model is a generic model of sequence data which is also been used to model financial time series [67] and purely theoretical chaotic dynamical systems [68]; the neural graph-based parser is simply solving a minimal spanning tree problem [60]. Nevertheless, it may be the case that a bias toward word order universals is somehow encoded implicitly in the hyperparameters and architectures of these models.

Here we address this question by demonstrating that our languages optimized for efficiency are also optimal under a range of different language models and parsers. These results show that our optimization process creates language in which strings are generally predictable and informative about trees, without dependence on particular prediction and parsing algorithms.

## S7.1 CKY Parsers

We constructed simple Probabilistic Context-Free Grammars (PCFGs) from corpora and word order grammars, using a simplified version of the models of [69] (Model 1). In our PCFGs, each head independently generates a set of left and right dependents. We formulate this as a PCFG where each rule has the form:

$$\text{POS}_H \rightarrow \text{POS}_H \text{POS}_D$$

for head-initial structures, and

$$\text{POS}_H \rightarrow \text{POS}_D \text{POS}_H$$

for head-final structures, where each symbol is a POS tag. Thus, POS tags act both as terminals and as nonterminals.

We estimated probabilities by taking counts in the training partition, and performing Laplace smoothing with a pseudocount  $\alpha = 1$  for each possible rule of this form. For such a PCFG, exact parsing is possible using Dynamic Programming, and specifically the CKY algorithm [70].

This parsing strategy is very different from the neural graph-based parser: While the graph-based parser solves a minimum spanning tree problem, the CKY algorithm uses dynamic programming to compute the exact probabilities of trees given a sentence, as specified by the generative model encoded in the PCFG. Second, while the graph-based neural parser uses machine learning to induce syntactic knowledge from data, the CKY parser performs exact probabilistic inference.

We used the CKY algorithm to compute the syntactic ambiguity  $H[\mathcal{T}|\mathcal{U}]$  on the validation partition of the English and Japanese UD corpora, for random and optimized ordering grammars. Results (Figure S6) show that optimized grammars are more parseable than baseline grammars, for exact parsing of a simple PCFG.

## S7.2 Distorted graph-based parsers

In this section, we address the idea that the graph-based parser might have a built-in bias toward certain kinds of orderings, and the question whether this might be responsible for our findings. In particular, we address the idea that the graph-based parser might have a bias toward parses involving short dependencies, which we call a **locality bias**. We address this by changing the order in which the parser sees words, in such a way that the distance between words in the input is not indicative of syntactic relations.

**Even-odd order.** A sequence of  $n$  words originally ordered as  $w_1 w_2 w_3 w_4 \dots w_n$  is reordered by separating the even and odd indices:  $w_2 w_4 w_6 \dots w_{n-1} w_1 w_3 w_5 \dots w_n$  (assuming  $n$  odd). Therefore all words that are adjacent in the original order will be separated by a distance of  $\approx n/2$  in the distorted order, while all words of distance 2 in the original order will become adjacent.

**Interleaving order.** In interleaving ordering, a sequence originally ordered as  $w_1 w_2 w_3 \dots w_n$  is split in half at the middle (index  $m = \lceil n/2 \rceil$ ), and the two resulting sequences are interleaved, yielding  $w_1 w_m w_2 w_{m+1} w_3 w_{m+2} \dots w_n$ . Thus all words that were originally adjacent will have distance 2 in the distorted order, with the intervening word coming from a very distant part of the sentence.

Figure S6: Parsing loss  $H[\mathcal{T}|\mathcal{U}]$  (lower is better) computed by a simple CKY parser, for random word order grammars (red) and word order grammars optimized for efficiency (blue). We report  $H[\mathcal{T}|\mathcal{U}]$  normalized by sentence length.

**Inwards order.** A sequence originally ordered as  $w_1 w_2 w_3 \dots w_{n-1} w_n$  is ordered from the edges of the string inwards, as  $w_1 w_n w_2 w_{n-1} \dots w_{\lceil n/2 \rceil}$ . This corresponds to folding the string in on itself once, or equivalently, splitting the sequence in half at the middle, then interleaving the two resulting sequences after reversing the second one. The result is that the most non-local possible dependencies in the original order become the most local dependencies in the distorted order.

**Lexicographic order.** A sequence is reordered by sorting by POS tags, and randomizing the order within each block of identical POS tags. To each word, we then add a symbol encoding the original position in the sequence. For instance

PRON VERB PRON

may be reordered as

PRON 1 PRON 3 VERB 2

or

PRON 3 PRON 1 VERB 2

The numbers are provided to the parser as atomic symbols from a vocabulary ranging from 1 to 200; numbers greater than 200 (which may occur in extremely long sentences) are replaced by an out-of-range token.

The result is that distance between words in the input is not indicative at all of the presence of absence of syntactic relations between them.

**Experiments** Using English and Japanese data, we trained parsers for ten random word order grammars and for the best grammar optimized for efficiency, with the input presented in each of the distorted orderings. Resulting parsing scores are shown in Figure S7. In all settings, the language optimized for efficiency achieved lower parsing loss (i.e., higher parseability) than random ordering grammars, showing that the parser’s preference for optimized languages cannot be attributed to a locality bias.

### S7.3 n-gram language models

We model predictability using LSTM language models, which are the strongest known predictors of the surprisal effect on human processing effort [71, 72]. In previous work, such as [46], predictability has often been measured using n-gram models.

Here, we show that languages optimized for LSTM predictability are also optimal for n-gram predictability. Specifically, we constructed bigram models with Kneser-Ney smoothing [73, 74]. A bigram model predicts each word taking only the previous word into account. This contrasts with LSTMs, which take the entire context into consideration. Thus, bigram models and LSTMs stand on opposing ends of a spectrum of language models taking more and more aspects of the context into account.

We estimated language models on the training partitions, and used the validation partitions to estimate surprisal. We conducted this for ten random and the best optimized ordering grammars on English and Japanese data. Results (Figure S8) show that languages optimized for efficiency are also optimal for a bigram language model.

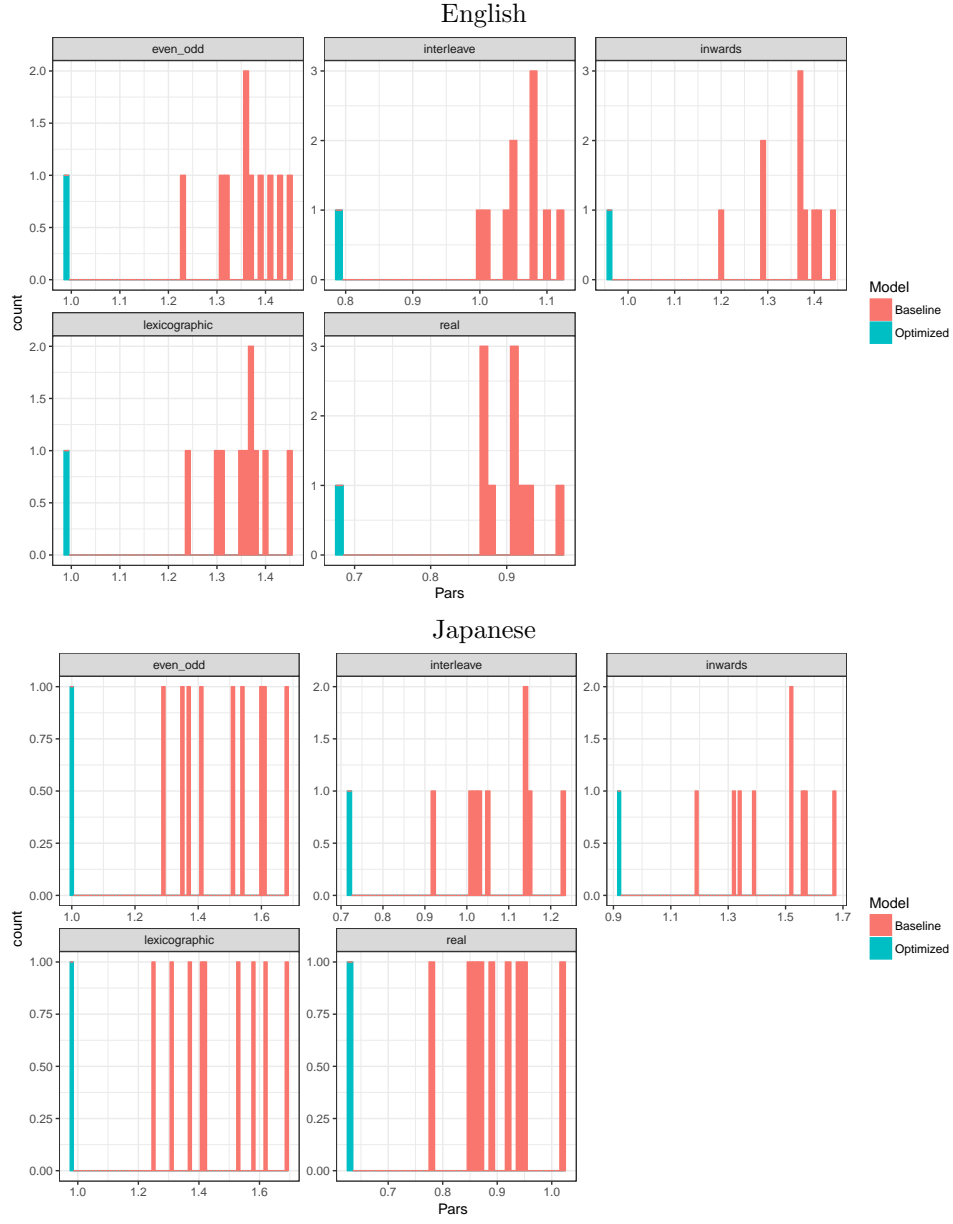

Figure S7: Parseability of baseline grammars and grammars optimized for efficiency, in English (top) and Japanese (bottom), measured by parsing loss  $H[\mathcal{T}|\mathcal{U}]$  (lower is better), for the four distorted orderings, and the actual orderings ('real'). We report  $H[\mathcal{T}|\mathcal{U}]$  normalized by sentence length.

Figure S8: Surprisal (i.e., negative predictability, lower is better) computed from Bigram model, on English and Japanese data ordered according to random ordering grammars (red) and ordering grammars optimized for efficiency (blue).

## S8 Effects of data sparsity

Here, we investigate whether the difference between real and baseline grammars is affected by the size of available datasets. We are addressing the following confound: It is conceivable that with enough data, our neural network language models and parsers would do equally well on real grammars and baseline grammars. If the difference between random and real grammars is due to data sparsity in this way, then we expect that the difference will decrease as the amount of training data is increased. If, on the other hand, there is an inherent difference in efficiency between random and real grammars, we expect that the difference will persist as training data is increased.

We considered Czech, the UD language with the largest amount of available treebank data (approx. 2.2 Million words), up to  $\approx 300$  times more data than is available for some other UD languages. We considered both a random ordering grammar, and the best ordering grammar optimized for parseability. For both of these ordering grammars, we trained the parser on successively larger portions of the training data (0.1 %, 1 %, 5%, 10%, 20 %, ..., 90 %, 100 %) and recorded parsing accuracy. Furthermore, for the random grammar, we varied the number of neurons in the BiLSTM (200, 400, 800) to test whether results depend on the capacity of the network.

The resulting curves are shown in Figure S9. A gap in parsing loss of about 0.2 nats appears already at 0.01 % of the training data (2000 words), and persists for larger amounts of training data. This shows that the observed efficiency differences between grammars cannot be attributed to data sparsity.

Figure S9: Parsing loss ( $H[\mathcal{T}|\mathcal{U}]$ , normalized by sentence length) for optimized (light blue) and random (black) ordering grammar on Czech data, as a function of the fraction of total training data provided.

## S9 Languages and Corpus Sizes

In Table S9, we list the 51 languages with ISO codes and families, with the size of the available data per language. We included all UD 2.1 languages for which a training partition was available.

## S10 Dependency Length Minimization

Prior work has suggested *Dependency Length Minimization* (DLM) as a characteristic of efficient word order [5, 75, 76]. This is the idea that word order minimizes the average distance between syntactically related words. It is known that human languages reduce dependency length compared to random baselines [5, 75, 76]. Prior work has suggested principles akin to DLM as approximating efficiency optimization of grammars [77, 78, 23, 79]. It is a heuristic formalization of the idea that long dependencies should create high memory requirements in parsing and prediction [77, 80, 81, 23]. Indeed, [23] argues specifically that it emerges from efficiency optimization.

Dependency length is typically quantified as the average distance between all pairs of syntactically related words, measured by the number of intervening words [5]. Dependency length quantified in this manner is a heuristic measure of complexity: The actual empirically-measured processing complexity induced by long dependencies is not a linear function of length and depends crucially on the types of dependencies involved [82] and the specific elements intervening between the head and dependent [80, 81, 83].

We asked whether efficiency optimization predicts dependency length minimization effects. We first computed dependency length for grammars optimized for efficiency. We found that 100% of grammars optimized for efficiency reduce average dependency length compared to baseline grammars ( $p < 0.05$ , by one-sided  $t$ -test). This suggests that the reduction of dependency length observed in natural language is indeed predicted by efficiency maximization, confirming theoretical arguments made in prior work [77, 78, 23, 79]. Next, we constructed grammars that minimize average dependency length, using the same gradient descent method as we used for efficiency optimization (Section S5.3). We expect that such grammars should have shorter dependency length than the real grammars, or grammars optimized for efficiency. In Figure S10, we plot the mean dependency length for optimized, real, and baseline orderings. We find that optimizing grammars for efficiency reduces dependency length to a similar degree as found in the actual orderings in the corpora, almost up to the limit given by directly optimizing for dependency length. We also plot more detailed results for four languages in Figure S11, plotting dependency length as a function of sentence length as reported in prior work [5]. Optimizing grammars for efficiency produces dependency lengths similar to those found in the actual orderings.

Figure S10: Average dependency length for grammars optimized to minimize dependency length (DLM, left), optimized for efficiency (second), the real orderings found in corpora (third), and random baseline grammars (right). The lines connect the mean points for each of the 51 languages in our sample.

Next, we examined the word order properties of grammars optimized for DLM. In Table S10, we report the posterior prevalence of word order correlations in grammars optimized for DLM; our results show that optimizing for DLM makes predictions similar to efficiency optimization. This is itself a novel result, suggesting that it is in part through favoring

Figure S11: Total dependency length as a function of sentence length, for four diverse languages. We show results for optimized grammars (parseability, predictability, efficiency), for grammars specifically optimized to minimize dependency length, of the actual real orderings, and of the baseline grammars.

short dependencies that efficiency predicts word order universals, an idea that has been proposed in prior theoretical studies [77, 78]. We find that these grammars also exhibit the eight correlations, similar to grammars directly optimized for efficiency. On other correlations, predictions of DLM also resemble those of efficiency optimization. However, it predicts strong correlations with *amod* (adjectival modifiers) and *nummod* (numeral modifiers) (see bottom of Table S10), which are not borne out typologically. In these cases, efficiency optimization predicts prevalences closer to 50%, in line with typological data.

In conclusion, these results suggest that the phenomenon of dependency length minimization is a by-product of efficiency optimization, providing support to theoretical arguments from the linguistic literature [77, 23, 79]. Furthermore, optimizing for dependency length correctly predicts a range of word order facts, though it appears to *overpredict* correlations when compared to direct optimization for communicative efficiency.
